Carbon Dioxide Affects Charge Accumulation in Leaves

Measurements by Thermoluminescence

Warburg and Krippahl [1] discovered that CO$_2$ (or bicarbonate, HCO$_3^-$) was needed for the electron flow in the Hill reaction of plants and proposed (see discussion in [2]) that O$_2$ originated in CO$_2$, not H$_2$O. Although the phenomenon has been confirmed (see [3]) by many, the site of action of this CO$_2$ action has been shown to be not on the oxygen evolution, but on the electron acceptor site of the oxygen-evolving photosystem II (PS II) [4 – 6], where it participates in the reduction of plastocyanin by the bound quinone (Q$_A$). Blubbaugh and Govindjee [7] have shown that it is HCO$_3^-$, rather than CO$_2$, that is the active species involved in stimulating the electron flow in thylakoids. Bicarbonate has also been shown to affect ATPase of chloroplast thylakoid membranes [8].

In contrast to the wealth of information in vitro, i.e., in isolated thylakoids, in vivo data are scarce. Effect of partial CO$_2$ depletion and readdition of CO$_2$ was studied in leaves by flash-induced electrochromic absorbance changes at 515 nm (A515) and chlorophyll a fluorescence induction [9]. CO$_2$, possibly due to its effect on the ATPase ([8]; cf. also [10]), has been shown to affect the rise and decay of the absorbance transient, A515, which is proportional to the transmembrane electric field [11]. Furthermore, chlorophyll a fluorescence induction data in leaves suggested that CO$_2$ has a regulatory role at the electron acceptor site of PS II in leaves [9]. Recently, detailed analyses of chlorophyll a fluorescence induction data in leaves have shown that indeed CO$_2$ has a direct role in electron transport regulation in leaves [12]. Bicarbonate effects in intact algal cells had been shown earlier (see e.g. [6, 13]).

Govindjee et al. [14] have used thermoluminescence (TL) measurements in thylakoids to show that CO$_2$ depletion blocks the cycling of the electron acceptor site of PS II. We have investigated TL in leaves which were partially depleted of intercellular gases, including CO$_2$, and were incubated in N$_2$ or CO$_2$-enriched atmosphere. TL is a measure of charge recombination around PS II. Our results, presented here, show that CO$_2$ affects the charge accumulation process around PS II in leaves: it is suggested to deplete these charges because it stimulates the forward electron flow from PS II to photosystem I (PS I).

Spinach leaves were obtained from the local market in Szeged. The TL of leaf segments was measured essentially as described earlier [15] following protocol 1 or 2: (1) Leaves were depleted of
their intercellular gas content by infiltrating them with water under gentle vacuum for 5–20 min [9]. A disc of 7 mm diameter was cut from a leaf, placed onto the TL sample holder equipped with a gas chamber, and incubated in CO₂-enriched or N₂ atmosphere for 3 min in the dark before measurement. (We found that CO₂ atmosphere and CO₂-enriched atmosphere, i.e., CO₂ plus N₂ or air gave equivalent results)(2) The disc of 7 mm diameter was cut from non-infiltrated leaf, placed onto the sample holder and incubated in the gas chamber for various intervals in the dark or in the light. Samples were excited with white actinic light of 10 W m⁻² during cooling from 20°C to −60°C at a rate of 1.38°C s⁻¹. The glow curves were recorded between −60 and +60°C.

CO₂-Depleted Leaves. Figure 1 shows that partial depletion of the intercellular gas content and readition of CO₂ induces marked effects on the glow curves of infiltrated leaves. The major effect of the depletion process is the appearance of the 0°C band, and the major effect of CO₂ addition is its diminution; in contrast, N₂ addition enhances this band further. These effects develop quite rapidly, within several minutes, in the dark.

Fig. 1. Effect of gaseous environment (CO₂ or N₂) on the thermoluminescence (TL) of water-infiltrated spinach leaf discs; a) untreated leaf; N₂ and CO₂; leaves depleted of their intercellular gas content and incubated in the dark in N₂ or CO₂ atmosphere, respectively. Each TL curve was obtained by averaging three glow curves from independent experiments recorded under the same experimental conditions. (For other details, see description in the text, protocol 1)

Non-CO₂-Depleted Leaves. In samples where intercellular gases were not depleted (Fig. 2), incubation in CO₂ had apparently different effects: with 30–60-min preincubation in dark or just 1 min light and 5 min dark, the 0°C band increased in intensity; the TL pattern was, however, close to the original sample, i.e., it had a high 40°C and a low 0°C band. Incubation under N₂, however, gave qualitatively the same results as shown in Fig. 1 except that the 0°C band appeared at full intensity even after 1 min light and 5 min darkness. Preillumination apparently facilitated the rate of gas exchange between the leaf and its environment. In spite of the apparent difference in the CO₂ curves, a comparison with N₂ curves shows that the 0°C band was more dramatically reduced under CO₂ than under N₂ atmosphere, confirming the data of Fig. 1.

We emphasize that the effect of CO₂ in TL was observed mostly under such experimental conditions where interference from the carbon (Calvin) cycle can be ruled out. Preillumination was not necessary to obtain the effect of the readition of CO₂. Since CO₂ uptake at room temperature has a lag phase of about 5 s in intense light [16] and the leaves were excited only during the rapid cooling (at a rate of 1.38°C s⁻¹) between 20°C and −60°C, the chloroplasts could not have much chance for carbon metabolism.

The most easily recognizable difference between the two types of gas treatment was the integrated TL area (Table 1). This parameter, at least in a semi-quan-

titative way, measures the concentration of the charges residing around PS II. Since the contribution of the reduced plastoquinone in PS II is insignificant when compared to that by the reduced bound plastoquinones QA and QB, the two secondary electron acceptors of PS II, a decrease in TL intensity in CO2-enriched atmosphere suggests that CO2 facilitates the flow of electrons from the vicinity of QA and QB towards photosystem I (PS I). In the presence of N2 alone, the TL intensity is higher, suggesting the accumulation of QA and QB needed for charge recombination that produces TL. Although the TL peak positions varied somewhat from sample to sample, the following three major peaks could be identified: a peak around -15 °C (the so-called A peak); 0 to 10 °C (the so-called D or the Q peak); and 30 to 45 °C (the so-called B band, often made up of two peaks B1 and B2). The ratio of the intensity of the B band to the D (or Q) band, labeled in Table 1 as HT/LT, was elevated when CO2 was present. The same ratio decreased when N2 was present. The TL bands originate in recombination of QA or QB with the redox state of the oxygen-evolving complex (the electron donors of PS II), the so-called S states. Peak A is suggested to originate in S1, QA, D (or Q) in S2, QA, and B (B1 and B2) in S1, QA [17]. Thus, our results show that the absence of CO2 (presence of N2; or depleted of all gases) increases the ratio of QA to QB in leaves and CO2 has the opposite effect.

In conclusion, thermoluminescence of leaves has provided independent experimental evidence, without the use of inhibitory ions (such as formate or nitrite), often used in thylakoid studies, that CO2 in leaves facilitates the flow of electrons from the reduced QA towards PS I. This places the role of CO2 (HCO3-) in electron flow in vivo on a firm basis, a role totally different from that of the Calvin cycle, and explains the phenomenon discovered by Otto Warburg 30 years ago.
